ABSTRACT

Data-driven design of mechanical metamaterials is an increasingly popular method to combat costly physical simulations and immense, often intractable, geometrical design spaces. Using a precomputed dataset of unit cells, a multiscale structure can be quickly filled via combinatorial search algorithms, and machine learning models can be trained to accelerate the process. However, the dependence on data induces a unique challenge: An imbalanced dataset containing more of certain shapes or physical properties than others can be detrimental to the efficacy of the approaches and any models built on those sets. In answer, we posit that a smaller yet diverse set of unit cells leads to scalable search and unbiased learning. To select such subsets, we propose METASET, a methodology that uses similarity metrics and positive semi-definite kernels to jointly measure the closeness of unit cells in both shape and property spaces, and 2) incorporates Determinantal Point Processes for efficient subset selection. Moreover, METASET allows the trade-off between shape and property diversity so that subsets can be tuned for various applications. Through the design of 2D metamaterials with target displacement profiles, we demonstrate that smaller, diverse subsets can indeed improve the search process as well as structural performance. We also apply METASET to eliminate inherent overlaps in a dataset of 3D unit cells created with symmetry rules, distilling it down to the most unique families. Our diverse subsets are provided publicly for use by any designer.

1 Introduction

Metamaterials are drawing increased attention for their ability to achieve a variety of non-intuitive properties that stem from their intentionally hierarchical structures [1]. While they traditionally consist of one unit cell that is repeated everywhere, multiple unit cells can also be assembled to create aperiodic mechanical metamaterials with, e.g., spatially-varying or functionally-gradient properties [1, 2]. Over the past few years, conventional computational methods have been adapted to design these complex structures, including topology optimization (TO) of the microscale unit cells within a fixed macroscale structure [3, 4], and hierarchical and concurrent multiscale TO that design both the unit cell and macro-structure [5–7]. However, as the desire to attain even more intricate behaviors grows, so too does the complexity of the design process, which must account for the expensive physical simulations and, in aperiodic structures, the vast combinatorial design space and disconnected neighboring unit cells [1, 8].

Capitalizing on advances in computing power, data-driven metamaterials design can be a more efficient and therefore enticing solution to those challenges. Its success hinges on precomputed unit cell libraries or datasets, which can avoid costly on-the-fly physical simulations and multiscale TO in huge design spaces, as well as provide candidate unit cells that are better connected to their neighbors. Fig. 1 shows an overview of two common approaches in data-driven design: global optimization methods, and machine learning (ML) based methods. In the first case, combinatorial optimization algorithms can be used to directly search for the set of unit cells that realize a target macroscale behavior while minimizing or constraining the boundary mismatch between neighboring cells [1, 8–10]. From another perspective, data-driven methods can use the dataset to train ML models that further accelerate design. For example, they have been used to rapidly predict homogenized physical properties as part of the optimization loop [11–14]. Additionally, deep generative models inspired by
the computer vision field can learn embedded geometric descriptors that act as reduced dimensional design variables, and construct new designs, e.g., optical 2D metamaterials [15, 16], almost instantaneously.

The efficacy of data-driven methods, however, relies highly on the size and coverage of the datasets. The search space of global optimization methods can quickly explode when the number of unit cells increases. Meanwhile, imbalanced datasets with skewed data distributions can reduce the chance of meeting certain property or compatibility requirements, and hobble the performance of ML models since they may not learn a less frequent property or shape as well [17]. Therefore, due to the importance of the data on downstream tasks, in this work we focus on the first step of data-driven design: dataset selection.

In existing literature, metamaterial datasets are often built using heuristics or the designer’s intuition, with the assumption that the unit cells will offer sufficient coverage for the desired application. Many employ TO to inversely design unit cells that meet pre-specified target properties [1, 9, 11], and some expand the dataset by morphing the shapes [1, 11] or randomly flipping pixels or voxels [9]. Alternatively, Panetta et al. developed graph-based rules to create truss-like unit cells [18]. Although these are more feasible than enumerating over all possibilities, bias towards particular properties or shapes can be unintentionally introduced, deteriorating the performance of the design algorithm or the design itself.

Moreover, the point at which to stop generating new unit cells has thus far been heuristic with the same goal in mind: to cover a broad property space. The range of this space is sometimes restricted for specific applications [3], or strict symmetry and manufacturability constraints are implemented to limit the possible shapes [18]. More often, the property space is allowed to grow at will, e.g., TO and shape perturbation are repeated until the change in the density of the property space is less than a given tolerance [9, 11]. While efficient, all of the works to date have only considered coverage in the property space alone, which can produce similar shapes or overlook those that might benefit the design with regards to boundary connectivity. In contrast, our work explores coverage in both property and shape spaces.

Improving imbalance arising from data with multiple classes has been extensively researched in computer science. The most relevant to our application are the data-preprocessing strategies such as undersampling to remove data from majority classes, oversampling to replicate data from minority classes, or combinations thereof [17]. However, the former can accidentally remove samples with important features, i.e., decrease the diversity, and the latter can lead to model overfitting and increased training overhead [19]. Nor are they made to consider the diversity of data with features that have drastically different representations, like shape and property. The issue of downsampling a metamaterial database was addressed by Chen et al. [14], who compressed the size of their database by selecting the samples that are farthest from each other with respect to properties (not shape), allowing them to more efficiently fit a property prediction model. As far as we know, there is currently no method to assess or select a diverse set of unit cells that can simultaneously cover the shape and property spaces.

Despite the dearth in the metamaterials field, measuring and ranking items based on their quality as well as their contribution to the diversity of a whole set or subset is an ongoing research area. In computer science, for example, recommender systems rank diverse items such as online products to match users’ preferences. These are based on the concept of diminishing marginal utility [20], wherein lower ranking items bestow less additional value onto the users. In design, too, researchers have developed methods to help designers sift through large sets of ideas by ranking them. In particular, to balance diversity against quality of designs, Ahmed et al. introduced the idea of clustering items into groups for subset selection [21], which employed submodular functions that follow the property of diminishing marginal utility. Ahmed et al. [22] also showed the application of Determinantal Point Processes [23], which model the likelihood of selecting a subset of diverse items as the determinant of a kernel matrix, to the diverse ranking task. The latter, in particular, are elegant probabilistic models that
capture the trade-off between competing ideas like quality and diversity. While the goal of maximizing the determinant is similar to the optimality criterion used in generating D-optimal designs [24] in design of experiments, Determinantal Point Processes are not restricted to linear kernels and have advantages in that calculating marginals, computing certain conditional probabilities, and sampling can all be done in polynomial time. This paper shows that it can also be used for coverage in multiple spaces defined over the shapes and properties of unit cells.

**Our contributions:** We propose METASET, an automated methodology that simultaneously considers the diversity of shape and property to select subsets of unit cells from an existing dataset. By doing so, we can achieve scalable data-driven design of metamaterials using smaller yet diverse subsets. In addition, we can eliminate bias in imbalanced datasets through diversification to improve any downstream tasks, such as design or ML. As a part of METASET, we also introduce similarity metrics to efficiently assess the diversity of the shapes and properties of 2D and 3D metamaterials. We propose that a weighted sum of Determinantal Point Process (DPP) kernels based on the shape and property similarities can measure and allow the maximization of the joint diversity of both spaces. For the first time in data-driven metamaterials design — to our knowledge — using 2D design as example, we reveal that diverse subsets can expedite and even enhance the design performance and compatibility of aperiodic mechanical metamaterials compared to using the full dataset. Finally, applying METASET to the generation of 3D unit cells, we identify diverse families of isosurface unit cells and discover that these extend beyond the ones commonly considered in the design of functionally-graded structures [2, 25]. The diverse subsets are available publicly.

**Organization of the paper:** Our methods are detailed in Sec. 2. As case studies and validation, we apply METASET to diversify large datasets of 2D and 3D unit cells. We use the diverse 2D subsets to design metamaterials with non-intuitive target displacement profiles (Sec. 3). In the 3D case, we employ METASET to provide unique and diverse families of isosurface unit cells (Sec. 4).

## 2 METASET: Assessing and Optimizing Diversity

The inner workings of METASET consist of three main steps: 1) Defining similarity metrics for metamaterials that quantify the difference between pairs of 2D or 3D shapes and mechanical properties (Sec. 2.1); 2) Using a DPP-based submodular objective function to measure the joint coverage of a set of unit cells in shape and property spaces via pairwise similarity kernel matrices (Sec. 2.2); 3) Maximizing the joint diversity with an efficient greedy algorithm while allowing trade-off in the two spaces to be tuned to suit the desired application (Sec. 2.3). In this section, we describe these components and summarize the METASET methodology with Algorithm 1.

### 2.1 Similarity Metrics for Metamaterials

A diverse metamaterial dataset should ideally contain unit cells that are sufficiently different, i.e., dissimilar, such that they cover the shape and property spaces. To measure the diversity of a set, then, the similarities between the shapes and properties of unit cells first need to be quantified. We do so by defining metrics independently in each space, based on the observation that a set of unit cells dissimilar in shape space is not necessarily also dissimilar in property space, and vice versa. This can be illustrated by a simple example. Say we wish to distill diverse values from \( x \) and \( y \), which we assume to be sets of integers: \( x = \{0, 1, 2, 4, 5\} \) and \( y = \{0, 2, 10, 20, 10\} \). We assume that \( y = x * k \), where \( k = \{3, 2, 5, 5, 2\} \) is a transformation function. If we were to select three diverse values of \( x \), i.e., the values that most cover its space, we would select \( \{0, 2, 5\} \). For \( y \), however, we would choose \( \{0, 10, 20\} \) rather than \( \{0, 10, 10\} \), the ones corresponding to the diverse \( x \) values. Hence, though some relationship between two spaces may exist, e.g., an intrinsic function between shape and property, there is a need to model their coverage separately. For our design experiments discussed later, we further validate this observation by calculating the correlations between shape and property coverage, and find that no link exists between the two.

#### 2.1.1 Property Similarity

Since mechanical properties are generally scalar values that can be expressed as a vector, e.g., by flattening the elastic tensor, we can use any similarity metric between vectors. In this work, we use the Euclidean distance. We note that the properties do not need to be the tensor components; rather, they can be other values of interest such as elastic or shear moduli, or Poisson’s ratios. Neither do they need to be limited to scalar mechanical properties. For instance, dynamic acoustic bandgaps could be considered as long as the pairwise similarity can be quantified.

#### 2.1.2 Shape Similarity

Shape similarity metrics are key in many computer vision and graphics applications, e.g., object retrieval from databases and facial recognition. In these methods, the shapes are usually first represented by structural descriptors extracted from individual shapes [26], or by embedded features learned via data-driven methods such as clustering or ML [27]. The distances between features are then measured in either Euclidean [26] or Riemmanian space [28, 29]. Since Riemannian metrics are
based on geodesic distances, they are suitable if one needs invariance to deformation, \textit{i.e.}, if one considers a shape to be the same after bending.

For metamaterials, however, we must rule out deformation and rotation invariant metrics since any transformation of a unit cell impacts its properties. Additionally, to provide metrics that are compatible with small or imbalanced datasets, we avoid using embedded features in this work. We also seek techniques that are efficient — particularly in 3D — but still detailed enough to discriminate fine details, as well as able to form positive semi-definite similarity matrices for the later step involving DPPs. Hence, we introduce the following Euclidean metrics based on structural features, namely, division-point-based descriptors for 2D and Hausdorff distance for 3D.

\textbf{2D Shape Similarity Metric:} For 2D unit cells, which are typically binary images resulting from TO, there are multiple methods to compute similarities between them. We propose using a descriptor-based approach by first extracting a division-point-based descriptor \cite{30} to reduce the dimension of the image into a vector that extracts salient features at different levels of granularity. This has been applied to the field of optical character recognition \cite{31, 32}. The binary image of a unit cell is first recursively divided into sub-regions that contain an equal number of solid pixels. The coordinates of all division points, \textit{i.e.}, points at the intersection of two division lines between each sub-region, are then obtained as descriptors of the unit cell. This process is repeated until the desired level of detail is captured, constructing a \(k\)-d tree of the distribution of solid materials. In our 2D case study (Sec. 3), we perform the division seven times for each unit cell, which in our case extracts a sufficient amount of detail without needing a very high-dimensional descriptor. This results in the coordinates of 62 division points that constitute a 124-dimensional vector as the shape descriptor.

Using the above method, we can represent each 2D unit cell with a vector, then use the Euclidean norm to find the distance between any pair. However, the input for a DPP is a positive semi-definite similarity matrix, \(L\), so we transform the distance to a similarity metric through a radial basis function kernel with unit bandwidth, \(L_{i,j} = \exp(-0.5 \cdot d(i,j)^2)\), where \(d(i, j)\) is the distance between \(i\)-th and \(j\)-th unit cells. In practice, the choice of an appropriate transformation is equivalent to choosing the right distance metric between items. Our empirical study on other common transformations showed that different choices mainly affect the distribution of similarity values but do not significantly affect the final outcome or the key findings of our work.

\textbf{3D Shape Similarity Metric:} As for 3D unit cells, mesh formats such as STL are commonly used so that researchers can manufacture the metamaterials through additive manufacturing. However, since performing analysis on 3D shapes is undoubtedly more computationally intense, we suggest representing each unit cell as points on the surface of the original mesh, \textit{i.e.}, point clouds, which are more efficient for extracting and processing 3D features \cite{33}. This extra conversion can take little computation with well-established sampling methods, \textit{e.g.}, randomly sampling the surface of a mesh with the probability of choosing a point weighted by the area of the triangular faces.

We then use a distance metric commonly utilized to measure the distance between sets of points, the Hausdorff distance. In essence, it computes the difference between two clouds as the maximum of the nearest neighbor distances of each point. This is expressed as \cite{34}:

\[
\text{h}(A,B) = \max_{a \in A} \left( \min_{b \in B} ||a - b|| \right),
\]

where \(a\) is a point \((x,y,z)\) within cloud \(A\) and \(b\) is a point in the second cloud \(B\). The notation \(|| \cdot ||\) indicates that any distance can be used; for metamaterials, we use the Euclidean norm, \(||a - b||_2\). In our implementation, we computed the nearest neighbor norms using a GPU-enabled code by Fan \textit{et al.} \cite{35}. To obtain a symmetric distance, we take the maximum as follows:

\[
d_H(A,B) = d_H(B,A) = \max \left[ \text{h}(A,B), \text{h}(B,A) \right],
\]

Finally, we convert the pairwise distances into a DPP similarity kernel, \(L\), using the following transformation: \(L_{i,j} = \frac{1}{1 + d(i,j)}\).

\subsection{Determinantal Point Processes for Joint Diversity in Two Spaces}

Given a similarity kernel matrix \(L\), we can now measure the diversity of a dataset using Determinantal Point Processes (DPPs), which are models of the likelihood of choosing a diverse set of items. They have been used for set selection in ML, \textit{e.g.}, diverse pose detection and information retrieval \cite{23, 36}, and recently in ranking design ideas based on diversity and quality \cite{22}. Viewed as joint distributions over the binary variables that indicate item selection, DPPs capture negative correlations. This means that, intuitively, the determinant of \(L\) is related to the volume that the set covers in a continuous space. In other words, the larger the determinant, the more diverse the set.
To model our data, we construct DPPs through L-ensembles [37], using a positive semi-definite matrix $L$ to define a DPP. Hence, given the full unit cells dataset of size $N$, which we denote as ground set $G$, DPPs allow us to find the probability of selecting any possible subset $M$ of unit cells as:

$$P(M) = \frac{\det(L_M)}{\det(L+I)},$$  \hspace{1cm} (3)

where $L_M \equiv [L_{ij}]_{ij \in M}$ is the submatrix of $L$ with entries indexed by elements of the subset $M$, and $I$ is a $N \times N$ identity matrix. The probability of a set containing two items increases as the similarity between them decreases. Therefore, the most diverse subset of any size has the maximum likelihood $P(M)$, i.e., the largest determinant. For a fixed subset size, the denominator can be ignored when maximizing the diversity via an algorithm such as the one described in Sec. 2.3.

Unlike submodular clustering approaches, DPPs only require the similarity kernel matrix $L$ as an input, and do not explicitly need the data to be clustered or a function that models diversity to be defined. This also makes them more flexible, since we only need to provide a valid similarity kernel, rather than an underlying Euclidean space or clusters.

For METASET, we calculate two different similarity values — one in shape space and another in property space — between any two unit cells. Hence, for all the unit cells combined, we have one kernel matrix corresponding to each of the two spaces. In order to measure the joint coverage in both spaces, we take a weighted sum of the two matrices, thus allowing the trade-off between diversifying in shape or property space:

$$L = (1-w) \cdot L_P + w \cdot L_S,$$  \hspace{1cm} (4)

where $L$, $L_P$ and $L_S$ are, respectively, the joint, property and shape similarity kernels, and $w$ is a weight parameter than can be varied between 0 and 1. By adding the two kernels, we assume that the total similarity between two unit cells is the weighted average of how similar they are in the shape and property spaces.

While it is possible to combine two kernel matrices in many ways, we choose this formulation for two reasons. First, the weighted sum of two positive semi-definite matrices is also positive semi-definite, which is a pre-requisite for a DPP kernel. Second, it allows us to control the amount of diversity in both spaces, as well as to frame the later subset selection problem as multi-objective one, using a single tuning parameter $w$. We conducted multiple experiments on simulated data with easy-to-verify coverage metrics and found that this approach is effective in capturing diversity in both spaces. For brevity, we have not included these experiments here but directly report and discuss the results using joint kernels for metamaterials in Secs. 3.2 and 4.2.

**Algorithm 1:** METASET algorithm. After calculating the similarity kernels, a polynomial-time greedy maximization of the gain on the weighted combination between diversity in shape and property space is performed. The output is a subset of all unit cells such that the joint diversity is maximized.

### 2.3 Algorithm for Optimizing Diversity

Optimizing the diversity of a subset $M$ in two spaces is an inherently multi-objective problem that can be accomplished by maximizing the log determinant of the joint similarity kernel, i.e., $f = \log[\det(L_M)]$. Note that the log determinant of
a positive semi-definite matrix is monotonically non-decreasing and submodular. In general, finding the set of items that maximizes a submodular diversity function is NP-Hard. When solving such problems, a well-known limit due to Feige [38] is that any polynomial-time algorithm can only approximate the solution up to \( 1 - \frac{1}{e} \approx 67\% \) of the optimal.

However, this is where choosing a submodular function \( f \) as the objective comes in handy. It turns out that greedily maximizing this function is guaranteed to achieve the optimality bound. We use this property to substantially accelerate diversity optimization using a scalable greedy algorithm [39], which has theoretical approximation guarantees and is widely used in practice. At each step, the algorithm picks an item, i.e., a unit cell, that provides the maximum marginal gain in the objective function (lines 5-8 in Algorithm 1). This makes greedy maximization of diversity the best possible polynomial-time approximation to an otherwise NP-Hard problem.

Now that we have set the stage for METASET, we demonstrate through 2D and 3D mechanical metamaterials case studies the advantages of selecting diverse subsets of metamaterial unit cells based on their shape and properties. The most salient of these are the abilities to accelerate search algorithms while enhancing the final design performance (Sec. 3), and to discover unique unit cell families in order to build an economical and diverse dataset for design (Sec. 4).

3 METASET in Data-Driven 2D Metamaterials Design

Inserting METASET prior to the assembly stage in the general data-driven design flow (Fig. 1) can augment the performance and results of design search algorithms. In this section, we show the improvement through 2D data-driven design examples featuring mechanical metamaterials that are given target displacement profiles and constraints on the connectivity of neighboring unit cells. First, to emphasize that METASET can be added with little extra cost to any existing data-driven framework, we utilize a 2D dataset of unit cells from our previous work (which we briefly describe in Sec. 3.1). Next, we use METASET to select several subsets that demonstrate the effect of size and diversity on the search and final designs (Sec. 3.2). Finally, we employ these subsets to assemble full structures with two approaches — genetic algorithm for an illustrative study on the effect of subset size and diversity on designs (Sec. 3.3), and a two-stage method for a more complex design motivated by practical applications (Sec. 3.4). The designs, the classic MBB beam and a cantilever, are shown in Fig. 2 along with their boundary conditions and target displacement profiles (red curves). These types of structures, which require spatially varying elastic behavior, have applications such as soft robotic grippers and biomedical devices [1, 40], and have been a growing focus in recent research.

![Fig. 2: Problem settings of the 2D examples, both of which should achieve the target displacement profiles shown in red.](image)

3.1 Generation of 2D Unit Cells via Topology Optimization and Perturbation

In [11, 12], we previously proposed using a combination of TO and stochastic shape perturbation to generate a large dataset of 2D unit cells. To initialize the dataset, we ran density-based TO for each uniformly sampled target property, the components of homogenized elastic tensors, and then iteratively perturbed the shape of the unit cells with the most extreme or uncommon properties. By doing so, we created a dataset of 88,000 unit cells that covered a relatively large property space within reasonable computational cost. Note that we did not build this dataset with geometry in mind, leading to many similar shapes. Also, even though we aimed to fill the less populated regions of the property space by perturbing unit cells in those locations, there is a higher concentration of final unit cells with lower property values (the lower left corners in Fig. 4), indicating that the dataset is somewhat imbalanced. For details, please see [11].

Before applying METASET, we preprocess the data by randomly sampling unit cells from the original dataset that have a volume fraction greater than 0.70, resulting in 17,380 unit cells. This fraction was chosen so that the chosen unit cells are less likely to have very thin features, which makes them more feasible for manufacturing. Additionally, when computing shape diversity, if unit cells occupy very different volume fractions, a diverse subset is more likely to be dominated by flimsy, low density structures, whose shapes have the least probability of overlap with other unit cells. However, as we will show...
with the design examples, this preprocessing does not impede the chances of designing well-connected structures that met the targets quite well.

3.2 METASET Results: Diverse 2D Unit Cells

For the dataset of 17,380 2D unit cells, which we now refer to as the full or ground set $G$, we calculate the property and shape similarity matrices, $L_P$ and $L_S$, respectively, as described in Sec. 2.1. Taking their weighted sum forms the joint DPP kernel matrix $L$ (Sec. 2.2), whose determinant, $\text{det}(L_M)$, scores the diversity in both spaces. To explore this, we rank several subsets using the greedy algorithm from Sec. 2.3 by varying their sizes, $N_M$, and kernel weights, $w$. From the results, we can make three observations:

1. By increasing $w$, we shift from ranking a subset based on diversity in the property space alone, to a mixture of both spaces, and to the shape space only. In essence, trade-off between shape and property diversity can be easily controlled.

2. The correlation coefficient between the shape and property diversity scores of 1,000 random subsets of size five is 0.0047. Similar near-zero correlation is found for other set sizes too. In addition, the correlation between the shape and property similarity values of 100,000 random pairs of unit cells is $-0.0024$. Therefore, our assumption that the joint similarity can be modeled as a weighted sum is appropriate.

3. By observing the joint diversity score of the subsets as more items, i.e. unit cells, are added, we find that the gains in shape and property diversities saturate at approximately $N_M = 20$. Thus, a very small number of unit cells are sufficient to cover both spaces.

Ten example unit cells from the subsets with $w \in \{0, 0.5, 1\}$ are shown in Fig. 3, where the subset optimized for only shape diversity (Fig. 3c) displays the most variety of topologies compared to the subset diverse in only properties (Fig. 3a). Meanwhile, the balanced subset contains a mixture of unit cells akin to both extreme sets (Fig. 3b). This may be counter-intuitive since similar shapes should have similar mechanical properties. However, note that upon close inspection, the property diverse unit cells exhibit tiny features that lead to low elastic property values. Such small details in the shape may lead to a larger change according to the physical simulations and the property similarity metric, i.e., the Euclidean norm.

Comparing the properties of the unit cells in diverse subsets to the ground and randomly sampled sets (Fig. 4), we can confirm that the property diverse subsets cover all regions of the original property space, even the sparsely populated areas. As expected, the shape diverse subset does not do as well, and the random subset contains tight clusters in certain areas. Along with the observation that the diversity scores as well as the similarity values in the shape and property spaces are essentially uncorrelated, these findings confirm that the formulation of the joint kernel $L_M$ as a weighted linear sum (Eq. 4) is effective for controlling the amount of diversity in either space.

Finally, the result that only 20 unit cells is needed to cover the shape and property spaces is quite interesting since a main tenet of data-driven design thus far is that "more is better" — larger datasets provide more candidates from which we can choose compatible unit cells. So, to explore the impact of the subset size on the data-driven approach, we selected the top 20 as well as top 100 ranking unit cells from each subset to move on to the next step: full structure assembly.
3.3 Illustrative Study on the Effect of Size and Diversity

We begin by designing a relatively simple classical example from the TO field, the MBB beam, such that its horizontal centerline conforms to the red curve when loaded with a vertical force $F$ (Fig. 2a). Due to the structural symmetry, we only need to design the right half of the beam with $4 \times 4$ unit cells, outlined by the solid black lines. The full structure can then be obtained by reflecting over the vertical centerline. Using subsets of unit cells with varying sizes and levels of diversity for metamaterials design using global optimization, we can elucidate 1) the effect of subset size on the search algorithm’s efficiency, and 2) the impact of diversity on the final design performance as well as the compatibility of neighboring unit cells. We choose the following nine datasets:

- $P_{20}$: Property diverse subset of size 20
- $SP_{20}$: Shape and property diverse subset of size 20
- $S_{20}$: Shape diverse subset of size 20 diverse
- $R_{20}$: Random subset of size 20
- $P_{100}$: Property diverse subset of size 100
- $SP_{100}$: Shape and property diverse subset of size 100
- $S_{100}$: Shape diverse subset of size 100
- $R_{100}$: Random subset of size 100
- $G$: Full dataset of size 17,380

To design the MBB beam, we pass each of the datasets to a global optimization method, which for this example is a single objective genetic algorithm. Although the approach is simple, we chose it to focus on illustrating the effect of subset size and diversity on the final results. It also allows us to restrict our design to the discrete choice of unit cells in our subsets, whereas most gradient-based algorithms for data-driven metamaterials design map continuous design variables to the nearest existing, or interpolated, unit cell in dense databases [1, 9].

Specifically, the genetic algorithm is used to select the combination of unit cells from each given dataset that minimizes the mean squared error (MSE) between the achieved and target displacement profiles. In addition, since detached neighbours are not desirable, we add a compatibility constraint by requiring that the number of disconnected unit cells, $N_{dc}$, in the full structure be equal to zero. The optimization problem is formulated as:

$$\text{minimize} \quad \frac{1}{n} \| \mathbf{u}(I) - \mathbf{u}_t \|_2^2$$

subject to

$$K(I)\mathbf{U} = \mathbf{F},$$

$$N_{dc}(I) = 0,$$

$$I_i \in \{1, 2, \cdots, N_M\}, \quad i = 1, 2, \ldots, N_f,$$

where $\mathbf{u}$ is the displacement of $n$ nodes located on the centerline of the structure, $\mathbf{u}_t$ is the discretized target displacements, $K$ is the global stiffness matrix, and $\mathbf{U}$ and $\mathbf{F}$ are global displacement and loading vectors, respectively. The number of unit cells in the given dataset is $N_M$ while the number in the full structure is $N_f$, and $I = [I_1, I_2, \ldots, I_{N_f}]^T$ is a vector of the indices of the chosen unit cells.

Fig. 4: The property space of the 2D unit cell subsets optimized for property and shape diversity, and a randomly sampled set, plotted against the full dataset. We observe that property diverse subsets cover the space well, hence it is more likely to have unit cells near any target property combination.
Due to the stochasticity of genetic algorithms, we run the optimization ten times for each dataset and report the MSE of the final topologies in Fig. 5. In addition, we show a measure of the connectivity of the final structure: the mean ratio of disconnected pixels on the boundaries of touching unit cells, $r_{dc}$. Similar to $N_{dc}$ in the constraint (Eq. 5), a fully compatible structure should have $r_{dc}$ as zero. The averages of these results are also disclosed in Table 1. In Fig. 6, we show the final topologies of the runs that achieve the minimum MSE for some of the datasets.

![Fig. 5: The final objective values (MSE) and ratios of disconnectivity ($r_{dc}$) of 10 runs per subset. Lower values are better. The best overall MSE is obtained by SP$_{20}$ and S$_{20}$, and the best $r_{dc}$ by S$_{20}$ and SP$_{20}$.](image)

When given the full dataset, $G$, the search algorithm is overwhelmed and not able to find any designs with satisfactory MSE (see the high values in Table 1), even failing to meet the compatibility constraint in one run. This can be attributed to a vast search space since the number of possible unit cell combinations grows exponentially as the size of the dataset increases. A larger set may also contain more redundant shapes or properties that contribute little to diversity, exacerbating the search challenge and possibility of local optima. Conversely, every run using the 20- and 100-item subsets satisfy the design requirements. In fact, Fig. 5 and Table 1 highlight that smaller, diverse subsets consistently outperform all other sets under the same search algorithm and termination criteria. Notably, the lowest mean MSE is reached by the small SP$_{20}$ and S$_{20}$ sets. Moreover, the best connected structures, *i.e.*, those with lowest $r_{dc}$, result from the diverse subsets that consider shape, *i.e.*, S$_{20}$ and SP$_{20}$. We note that our optimization problem only constrains the number of disconnected unit cells and does not explicitly minimize $r_{dc}$. Therefore, the shape diverse results naturally attain higher connectivity.

As expected from the worse performance and compatibility, the topologies of the designs using the full dataset $G$ (not pictured) contain disconnected and oddly matched unit cells. In a similar vein, the high $r_{dc}$ for property diverse sets correspond to mediocre connectivity, as shown by the P$_{20}$ result in Fig. 6a, where neighbors are linked by tiny features. This can be associated with the observation in Sec. 3.2 that METASET tends to include unit cells with small features as it maximizes property diversity, leading to subsets with less compatible unit cells. With shape diverse subsets, however, the final designs possess excellent compatibility, such as in Fig. 6b, further enforcing the advantages of shape diversity.

Although our constrained genetic algorithm provides satisfactory designs, we must point out that this global method was implemented to showcase the impact of subset size and diversity. While more elegant optimization techniques would be better suited for practical applications, we nevertheless believe that the insights gained from this study — that selecting diverse subsets can accelerate and benefit metamaterial design — can be generalized to other data-driven methods, such as the one in the next section. This is an exciting direction for future works.
(a) Using property diverse subset of size 20 ($P_{20}$), the unit cells are connected, but by small features.

(b) Using shape diverse subset of size 20 ($S_{20}$), we observe superior connectivity between neighboring unit cells.

Fig. 6: Final topologies of the classical MBB beam example with the lowest MSE out of 10 runs using 20-item diverse sets. The full structure after symmetry is shown.

3.4 Application to Complex Metamaterial Structure Design

In the previous section, a simple example using genetic algorithm demonstrated that data-driven metamaterials design can benefit from small and diverse subsets of unit cells. To validate that this is also true for more sophisticated algorithms and designs, we now test the same hypothesis by combining our diverse subsets with an optimization method we proposed in [11], which is described briefly below. Here we design a cantilever composed of $4 \times 30$ unit cells to achieve a sine-wave shape when a prescribed displacement boundary condition is imposed (Fig. 2b). As opposed to the MBB beam, the spatially varying behavior of the cantilever is designed to deform in opposite directions in the left and right halves, and we expect that different regions in the structure will require distinctly contrasting properties. Due to the difficulty of this problem, or indeed any realistic metamaterials design, searching over larger datasets to locate compatible unit cells while meeting the desired performance is extremely expensive or even intractable. In our case, we are only able to use the smaller diverse subsets $S_{20}$, $SP_{20}$ and $P_{20}$ introduced earlier, as well as random subsets $R_{20}$. Since there are 120 macro-elements in the cantilever, this still means that there are $120^{20}$ possible combinations of unit cells for each subset.

For this example, we follow our two-stage optimization framework [11], wherein inverse TO is utilized in the first stage to determine the macroscale property distribution, and combinatorial optimization based on weighted graphs is used in the second stage to assemble unit cells that meet the target properties with compatible boundaries. Specifically, we define the following optimization problem for the first stage:

\[
\begin{align*}
\text{minimize} & \quad \frac{1}{n} \left\| \mathbf{u}(\mathbf{l}) - \mathbf{u}_{t} \right\|_{2}^{2} \\
\text{subject to} & \quad \mathbf{K}(\mathbf{C}_{e}) \mathbf{U} = \mathbf{F}, \\
& \quad -\phi(\mathbf{C}_{e}) \leq 0. 
\end{align*}
\]

(6)

Compared to the problem solved via genetic algorithm in the previous section (Eq. 5), this inverse property design directly uses the element stiffness matrix $\mathbf{C}_{e}$ as design variables, which are constrained by the signed L2 distance field $\phi$ of the property space of the full subset $G$. This inverse problem can be efficiently solved with the method of moving asymptotes (MMA) [41].

After obtaining the optimized macro-property distribution, we construct a grid-like weighted graph with each node representing an element in the macrostructure, and with edges connecting neighbouring unit cells. We can then view the assembly problem as selecting an index from the given subset to label each node in the graph. The Euclidean distance to the target property is assigned as the nodal weight during this process, and the ratio of disconnectivity, $r_{dc}$, defined in the last
section, is assigned as the edge weight for each pair of neighboring nodes. With this graph, we can use a dual decomposition Markov random field (DD-MRF) method [42] to efficiently find the optimal labels of the graph with the lowest sum of nodal
and edge weights, thereby designing a full structure that meets the target properties and is well-connected.

Since the labeling problem for the graph is a complex combinatorial optimization process where a large candidate set of unit cells equates to an immense search space, a small subset is required for a higher efficiency. As aforementioned, we use \( S_{20}, SP_{20}, P_{20} \) and five randomly selected subsets \( R_{20} \) with 20 unit cells as the candidate sets for the second stage. The resulting full structures and their respective MSE values and displacement profiles are shown in Fig. 7. We repeat the design using random subsets five times, then plot the mean displacement profile and depict the fluctuation of the results with the shaded area.

![Fig. 7: Optimized structures using different subsets, and their associated displacement profiles, for the cantilever example.](image)

By virtue of our weighted graph method, all optimized designs have compatible boundaries. However, the subsets which account for shape diversity, i.e., \( S_{20} \) and \( SP_{20} \), include a wider variety of unit cells in the full structure. This can be credited to an observation we made in the previous MBB beam example, that a shape diverse set can provide more compatible pairs, rendering a larger feasible design space for the assembly problem. In addition, we note that although some random subsets can achieve relatively low MSE, this performance is not guaranteed; the mean MSE is still the worst overall. In contrast, the shape and property diverse subset \( SP_{20} \) has the lowest MSE value. The reason is that, even with small subsets, shape diversity provides better compatibility while property diversity helps to achieve the target property distribution. This is again in line with our findings that a small yet diverse subset considering shape and properties is a boon for data-driven metamaterials design.

4 Discovery of Diverse 3D Unit Cell Families

Beyond selecting diverse subsets for direct use in design, another advantage of METASET is eliminating inherent bias by optimizing the diversity of a dataset. We demonstrate this with a 3D study, first introducing a new method based on periodic functions to generate families of unit cells with the same underlying structure but varying densities, which although fast creates a great number of overlapping shapes. Our goal in applying METASET to this 3D data is to sift through the overlaps to discover diverse sets of unique isosurface families, which can subsequently be leveraged for data-driven design or ML of, e.g., property prediction or generative models (Fig. 1).

Triply periodic isosurface unit cells, whose symmetries follow those of crystal structures [43], are often used in 3D mechanical metamaterials design due to excellent surface area-to-performance ratios and manufacturability [2]. In addition, their representation as level-set functions allows the density of the unit cells to be easily manipulated for functionally-graded structures [2, 25] and tailorable acoustic bandgaps [44]. A level-set function \( f(x,y,z) = t \) is an implicit representation of geometry where the \( t \)-isocontour, i.e., the points where \( f = t \), describes the surface of the structure, while the locations where \( f < t \) are solid material, and void where \( f > t \). Thus, by varying the isovalue \( t \), an entire family of isosurface unit cells can be extracted from one level-set function.

The most prevalent type of isosurfaces used in metamaterials design is a special subset known as Triply Periodic Minimal Surfaces (TPMS). However, only a few TPMS families have been used since their functions are complex to derive [43]. For example, Maskery et al. use six families in their design work [2], while Li et al. use four [25]. Moreover, it has not been investigated whether these few families cover the gamut of shapes and properties needed for design applications. Suppose a
researcher wishes to design a new functionally-graded 3D metamaterial by tuning the densities of isosurface functions, but does not know beforehand which families would best suit their application. Due to the computational expense of design in 3D, they may desire to select a smaller set of families that can then be used in their optimization method. In this section, we present METASET as a procedure to choose those families such that the resultant subset has large coverage over different properties and shapes. In doing so, we also demonstrate that METASET removes bias in datasets by maximizing diversity.

4.1 Generation 3D Unit Cell Families using Level-Set Functions

Before selecting diverse families, we must first generate an initial pool to choose from. Thus, to build a large 3D dataset, we propose a new method to create isosurface families based on the level-set functions of crystallographic structure factors, which describe how particles are arranged in a crystal unit cell [45]. In contrast to most unit cell generation methods, our approach here does not set targets in the property space or use TO, and different from TPMS functions, a larger variety of shapes can be found without complex derivations.

![Isosurface Families Images](image)

Fig. 8: Examples of unit cells from isosurface families generated by the structure factor for space group No. 229 and \((hkl) = (001)\). The effect of increasing \(t\) to create a family is shown from left to right.

In crystallography, structures that are invariant under the same symmetry operations belong to the same space group, of which there are a total of 230 for 3D structures. For the purposes of our work, we will focus on the 36 cubic groups, No. 195 through 230, to obtain our level-set functions. Experimentally, the space group of a crystal can be determined through, e.g., X-ray techniques, by scattering radiation off a lattice plane denoted by \((hkl)\), and then observing the diffraction pattern. These symmetric patterns have been analytically modeled as structure factors, which are periodic functions of the form:

\[
f_{\text{group},(hkl)}(X, Y, Z) = A + iB,
\]

where \(A = \cos(hX + kY + lZ)\), \(B = \sin(hX + kY + lZ)\), \(X = 2\pi x\), \(Y = 2\pi y\), and \(Z = 2\pi z\). The equations of these structure factors are listed in [45] for all space groups and their allowable \((hkl)\).

We can split each structure factor into six isosurface families by separating \(A\) and \(B\) in Eq. 7 (inspired by [43]), and converting them into level-set functions as follows:

\[
\begin{align*}
A_{\text{group},(hkl)}(X, Y, Z) &\leq t, \\
A_{\text{group},(hkl)}(X, Y, Z) &\geq t, \\
A^2_{\text{group},(hkl)}(X, Y, Z) &\leq t^2,
\end{align*}
\]

and similarly for \(B_{\text{group},(hkl)}\). These, respectively, correspond to setting as solid material the function values that are less than \(t\) (Fig. 8a), greater than \(t\) (Fig. 8b), and in between \(-t\) and \(t\) (leading to a “thin-walled” structure; Fig. 8c).

Thus, instead of using the limited TPMS functions, we can use the structure factors of all 36 cubic space groups and their corresponding \((hkl)\) to generate a greater number of isosurface families for data-driven design. In this way, we quickly
created 483 families without performing property-driven optimization. Although efficient, this method also causes an imbalance in geometry, since several structure factors differ only by a coefficient and lead to overlapping families. For example, space groups No. 195 and 196 are related as \( A_{195, (hkl)} = 4 \cdot A_{196, (hkl)} \), and therefore generate the same structures. Next, we demonstrate the prowess of METASET in systematically removing such overlaps when selecting diverse subsets.

4.2 METASET Results: Diverse 3D Families

As the families are comprised of a range of densities and therefore shapes and properties, we need to capture the similarities of individual unit cells while assessing the similarities between families. Hence, we generate 100 samples from each family covering all densities between 0.01 and 0.99, giving 48,300 unit cells total. Each unit cell is represented as a 4096-dimensional point cloud by first converting its level-set field into a triangle mesh [46], and then sampling uniformly on the triangular faces [47]. We also remove any small disconnected features during post-processing, and find the homogenized elastic tensors of each unit cell using a code modified from [48].

![Fig. 9](image)

Fig. 9: Trade-off between diversity in property vs. shape spaces. The minimum diversity in shape space for optimized sets has a diversity score greater than 98.9% of random samples.

To quantify the similarity between two families, we assume each family is a collection of points, where each point corresponds to a unit cell. This reduces the problem of finding similarity between two families to one between two point sets, which we calculate using the Hausdorff distance (Sec. 2.1.2). In property space, the similarity between two families is related to the maximum of the pairwise Euclidean distances between the effective elastic tensor components of each unit cell. For shape similarity between families \( C \) and \( D \), we take the Hausdorff distance twice: first using Eq. 2 to calculate \( d_H(c, d) \) between individual unit cells \( c \in C \) and \( d \in D \), and then substituting this into Eq. 1 to obtain the inter-familial distance, \( h(C, D) \). Intuitively, this means that the shape similarity between two families is the maximum of the similarities between closest-in-shape pairs of unit cells. Therefore, rather than simply averaging the features of each family, the inter-familial similarities also consider the diversity of unit cell members within each family.

Our goal is to find a small subset of 10 families out of 483 that are diverse in both the shape and property spaces. Using Eq. 4, we vary the weight \( w \) between 0 and 1, and run the greedy algorithm (Sec. 2.3) for each weight to find the optimal subsets. Next, we calculate the diversity of each subset in both property space (determinant of \( L_P \)) and shape space (determinant of \( L_S \)). As a baseline, we also randomly sample 1000 sets of families and measure their diversity in each space as well. Fig. 9 shows these diversity scores. Despite drawing several random subsets (which are representative of the distribution of the similarity values between pairs of unit cells), 98.9% of them still fall short of the optimized subset with the lowest shape diversity score. This is compelling evidence that 1) the original randomly generated dataset was severely imbalanced, and 2) METASET is able to combat such bias and select more diverse subsets. Additionally, the optimized scores (our method) in Fig. 9 illustrate the trade-off between the shape and property similarity metrics: the diversity in property space drops as we select sets that are more diverse in shapes, and vice versa. This can be leveraged to tune the dataset to specific applications, e.g., finding optimal designs or ML.

We point out that the trade-off might raise this question: How can a set of families which are quite diverse in property space have low diversity in shapes, even though similar shapes are expected to possess similar properties? On careful inspection of the left side of Fig. 9, one can notice that the sets of families with higher diversity in property space and
(a) Families diverse in property space

(b) Families diverse in shape and property spaces

(c) Families diverse in shape space

Fig. 10: Examples of subsets of 3D isosurface families selected by METASET.

seemingly “low” diversity in shape space actually have larger shape diversity scores than the majority of the random sets. This shows that the highest diversity in property space is achieved by a set of families which are also very diverse in shape. An interesting avenue of future research is whether the Hausdorff distance can affect this trade-off front. Using Hausdorff, we observed that even if two families have near complete overlap, with just one outlier, they can still have a large distance between them. While this property is mathematically desirable, and widely used in measuring similarity between point clouds, further research is needed to understand if this metric is the most appropriate choice for design applications.

Some example subsets of diverse isosurface families are shown in Fig. 10, where the 50th (median) sample from each family are pictured. Intriguingly, we note that in the shape diverse set (Fig. 10c), families generated from the same space group and \((hkl)\), but different level-set forms (Eq. 7) appear. For example, the second and third to last items in Fig. 10c have the equations \(A_{203,(111)} \geq t\) and \(A_{203,(111)} \leq t\). One could think of these as completely different shapes with almost no overlaps—which is further validation of the shape diversity chosen by METASET.

Moreover, the property-only and shape-only diverse sets (Figs. 10c and 10a, respectively) share very few of the same families, while the set that is equally shape and property diverse (Fig. 10b) contains a mixture of the former two. Common TPMS used for metamaterials design, such as the Primitive, Gyroid and Diamond (see [2, 25]) are also included among our diversified families. We provide the data of the METASET results publicly so that the diverse families can be employed by any designer in their work as well. For example, these can be directly utilized in existing functionally-graded design methods such as [25]. Data-driven design with diverse isosurface families will be investigated in future works.

5 Discussion

Although we illustrated the benefits of METASET with several case studies, there are nevertheless some topics worthy of examining in the future. From our design of 2D aperiodic structures, we saw that shape diverse subsets may increase the chance to find compatible neighboring unit cells, while property diverse sets might enhance problems that require a wider range of target properties at the cost of connectivity. This dependence on shape vs. property diversity extends to ML tasks in the data-driven design framework (Fig. 1) as well. To train property prediction models, one may need a property diverse dataset, while for a deep generative model that learns geometric features, a shape diverse set might be more appropriate. Along these lines, it would be interesting to further validate the improved performance of diverse datasets for design and ML tasks using our subsets of diverse 3D unit cell families in a future work.

In the 2D examples, we also observed that smaller subsets led to designs with performance closer to the targets; in fact, we found using METASET that only 20 unit cells were enough to form a diverse subset. In most cases, the benefits of reducing the search space, model training time, or storage requirement of the dataset could outweigh any loss of data. However, certain applications such as ML may need large datasets. A key benefit of using a METASET, even for large subset sizes, is that it reduces bias by rank ordering all items in the dataset. The items with the highest redundancy in shape or property (like duplicates) are pushed towards the end of the rank-ordered list, so that ML algorithms trained on any subset will be less biased. While it is not difficult to increase the size of the set, determining how much data is enough is more challenging since this too is contingent on the application. The effectiveness of size and diversity on specific tasks in metamaterials design is an important question for future studies. Fortunately, the ease at which a subset’s size as well as the weight of shape and property diversity can be explored is yet another advantage of METASET.

Finally, we remark that the capability of METASET depends on the choice of similarity metrics as well as the definition of the joint similarity kernel, both of which are avenues of further research. In this work, the 2D descriptors and Hausdorff
distance worked well in measuring shape similarity, but there are a wealth of other choices that may provide different results. Extending METASET to more complex properties, like dynamic ones, may necessitate a metric other than the Euclidean norm. For the joint DPP kernel, we chose a simple weighted sum to join the shape and property matrices, thereby casting the greedy selection as a multi-objective problem. We found in Sec. 3.2 that this was a valid assumption, but other methods to combine kernels while preserving submodularity are also possible. However, swapping these to best suit the application is easily done since the input of the DPPs-based greedy algorithm in METASET is a positive semi-definite similarity kernel that can be obtained from any appropriate metric or definition.

6 Conclusion

In this paper, we propose a methodology, METASET, that incorporates joint diversity in the shape and property spaces into data selection to improve the downstream tasks in data-driven design. It is efficient and flexible, allowing the emphasis on either shape or property to be easily traded by measuring and maximizing the joint diversity of subsets through a weighted DPP similarity kernel. To calculate this kernel matrix, we introduced similarity metrics that cater specifically to 2D and 3D metamaterials. Although in this work we focused on the design of mechanical metamaterials, we note that METASET can be transferred to other metamaterial domains, or indeed any other design problems that need to balance design space against some performance or quality space.

By way of our 2D aperiodic metamaterial design examples, we demonstrated that small yet diverse subsets of unit cells can boost the scalability of search algorithms, and lead to designs that better achieve target properties with greater boundary compatibility. This revelation shares a common belief in the field of data-driven mechanical metamaterials design that a larger and denser dataset is required to design well-connected structures while still meeting the target performance. To our knowledge, this is the first time that such a result has been studied and presented.

In our 3D case study, we not only proposed a new method to generate triply periodic isosurface families using crystallographic structure factors, but also verified that METASET can effectively reduce imbalance in metamaterial datasets. Similar to well-known TPMS unit cells, each of our 3D families are represented as level-set functions whose density parameter can be easily manipulated to design functionally-gradient metamaterials, or to tune an individual unit cell for greater compatibility with its neighbors. Different from established works, however, our dataset of families are optimized for shape and property diversity using METASET rather than arbitrarily chosen. In future works, we will explore the use these diverse families for data-driven metamaterials design and ML.

The methods proposed in this paper to achieve simultaneous diversity for shape and property is broadly applicable to domains outside data-driven metamaterials design, too. In design ideation, our method can be used to select ideas to show to a designer that are functionally different from each other while achieving different performance goals. It can also be integrated with existing multi-objective optimization algorithms as a niching method. To contribute to the growth and capability of data-driven metamaterials design methods and other fields, we have shared diversified subsets of 2D and 3D unit cells, as well as the corresponding equations of isosurface families. These unit cells can be directly plugged into the application of any metamaterials designer.
